

APPARATUS FOR GENERATING CODES
IN COMMUNICATION SYSTEM

PRIORITY

5

This application is a continuation of Application No. 10/074,422, filed February 12, 2002, the contents of which are incorporated herein by reference.

This application claims priority to an application entitled "Apparatus and
10 Method for Generating Codes in Communication System" filed in the Korean Industrial Property Office on February 13, 2001 and assigned Serial No. 2001-8275, and to an application entitled "Apparatus and Method for Generating Codes in Communication System" filed in the Korean Industrial Property Office on February 14, 2001 and assigned Serial No. 2001-7357, the contents of both of
15 which are hereby incorporated by reference.

BACKGROUND OF THE INVENTION

1. Field of the Invention

20 The present invention relates generally to code generation in a data communications system, and in particular, to an apparatus for generating complementary turbo codes, considering the characteristics of turbo codes in a packet communications system or a general communications system that employs a retransmission scheme.

25

2. Description of the Related Art

In general, a system using a retransmission scheme (e.g., HARQ: Hybrid Automatic Repeat Request) performs soft combining to improve transmission throughput. The soft combining techniques are divided into packet diversity
30 combining and packet code combining. These two combining schemes are

usually called soft packet combining. Although the packet diversity combining scheme is sub-optimal in performance relative to the packet code combining scheme, it is favorable due to easy implementation when performance loss is low.

5 A packet transmission system uses the packet code combining scheme to improve transmission throughput. A transmitter transmits a code with a different code rate at each packet transmission. If an error is detected from the received packet, a receiver requests a retransmission and performs soft combining between the original packet and a retransmitted packet. The
10 retransmitted packet may have a different code from the previous packet. The packet code combining scheme is a process of combining received N packets with a code rate R to a code with an effective code rate of R/N prior to decoding, to thereby obtain a coding gain.

15 With regard to the packet diversity combining scheme, on the other hand, the transmitter transmits the same code with a code rate R at each packet transmission. If an error is detected from the received packet, the receiver requests a retransmission and performs soft combining between the original packet and the retransmitted packet. The retransmitted packet has an identical
20 code to that in the previous packet. In this sense, the packet diversity combining scheme can be considered the received symbol energy averaging on a random channel. The packet diversity combining scheme reduces noise power by averaging the soft outputs of the received input symbols and achieves such a diversity gain as offered by a multi-path channel because the same code is
25 repeatedly transmitted on a fading channel. However, the packet diversity combining scheme does not provide such an additional coding gain as obtained according to a code structure in the packet code combining scheme.

A turbo encoder for generating the turbo code will be described herein
30 below. In the case of a turbo encoder with $R=1/5$, the turbo encoder generates

information symbols X , first parity symbols Y_0, Y_0' and second parity symbols Y_1, Y_1' by encoding input information symbols. The turbo encoder is comprised of two constituent encoders and one interleaver. The first parity symbols Y_0 and Y_0' are output from a first constituent encoder by encoding the input information
 5 symbols and the second parity symbols Y_1 and Y_1' from a second constituent encoder by encoding the information symbols interleaved through the interleaver. In detail, the Y_0 is a row of first parity symbols generated from a first constituent encoder, and the Y_0' is a row of second parity symbols generated from the first constituent encoder.

10

Due to implementation simplicity, most packet communication systems have used the packet diversity combining scheme, which is under study for application to the synchronous IS-2000 system and the asynchronous UMTS system. The reason is that the existing packet communication systems have
 15 used convolutional codes and even packet code combining does not offer a great gain when convolutional codes with a low data rate are used. If a system with $R=1/3$ supports retransmission, there is not a wide difference in performance between the packet code combining scheme and the packet diversity combining scheme. Thus, the packet diversity combining scheme is selected considering
 20 implementation complexity. However, use of turbo codes as forward error correction codes (FEC) requires a different packet combining mechanism because the turbo codes are designed as error correction codes to have performance characteristics very close to the "Shannon Channel Capacity Limit" and their performance varies obviously with the coding rates unlike
 25 convolutional codes. Therefore, it can be concluded that packet code combining is desirable for a packet communication system using turbo codes in a retransmission scheme to achieve the goal of optimum performance.

30

SUMMARY OF THE INVENTION

It is, therefore, an object of the present invention to provide an apparatus for generating sub-codes that enable optimum code combining in a retransmission system using turbo codes.

It is another object of the present invention to provide an apparatus for generating complementary codes using turbo codes in a communication system.

10 It is a further object of the present invention to provide an apparatus for generating sub-codes to be generated after channel interleaving in a retransmission system using channel interleaving.

The foregoing and other objects of the present invention are achieved by providing a QCTC (Quasi-Complementary Turbo Code) generating apparatus. In the QCTC generating apparatus, a turbo encoder has a plurality of constituent encoders and at least one interleaver and generates an information symbol sequence and a plurality of parity symbol sequences according to a given code rate by encoding the information symbol sequence. The constituent encoders generate the plurality of parity symbol sequences, each of the constituent encoders generates at least one parity symbol sequence, and the at least one parity symbol sequence from one constituent encoder corresponds to the at least one parity symbol sequence from another constituent encoder. A channel interleaver individually interleaves the information symbol sequence and the parity symbol sequences, alternately arranges the symbols of the corresponding parity symbol sequences, and serially concatenates the interleaved information symbol sequence and the arranged parity symbol sequences. A QCTC generator generates a sub-code of a QCTC by repeating the serially concatenated symbol sequence and selecting a predetermined number of symbols from the repeated symbol sequence according to code rate and selection information.

BRIEF DESCRIPTION OF THE DRAWINGS

5 The above and other objects, features and advantages of the present invention will become more apparent from the following detailed description when taken in conjunction with the accompanying drawings in which:

FIG. 1 is a schematic block diagram of a QCTC (Quasi-Complementary Turbo Code) generating apparatus according to the present invention;

10 FIG. 2 is a block diagram of an embodiment of the QCTC generating apparatus according to the present invention; and

FIG. 3 is a block diagram of another embodiment of the QCTC generating apparatus according to the present invention.

15 DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENTS

Preferred embodiments of the present invention will be described herein below with reference to the accompanying drawings. In the following description, well-known functions or constructions are not described in detail since they
20 would obscure the invention in unnecessary detail.

The present invention provides a QCTC generating method for a system using channel interleaving and a method of generating QCTCs in a predetermined way irrespective of a variable code length in a system requiring
25 QCTCs with a variety of code rates. A QCTC is defined as a complementary code generated using a turbo code. The QCTC is not a perfect complementary code as noted from the term "quasi" because a sub-code includes repeated symbols and has a different characteristic such as error correcting capability from another sub-code.

30

FIG. 1 is a schematic block diagram of a QCTC generating apparatus according to the present invention. The QCTC generating apparatus shown in FIG. 1 is characterized by carrying out symbol sequence repetition and puncturing after channel interleaving when generating sub-codes.

5

Referring to FIG. 1, an encoder 101 generates code symbols by encoding an input encoder packet. A convolutional encoder or a turbo encoder can be used as the encoder 101. The encoder 101 has a code rate of, for example, 1/5.
 10 For the input of 3,072 information bits, the encoder 101 outputs 15,360 code symbols. A channel interleaver 102 interleaves the code symbols according to a predetermined rule. If the encoder 101 is a turbo encoder, the interleaver 102 interleaves information symbols X , and parity symbols Y_0 , Y_1 , Y_0' , and Y_1' separately. A QCTC generator 103 generates sub-codes by puncturing and
 15 repeating the interleaved symbols. The channel interleaver 102 and the QCTC generator 103 perform the QCTC generation process.

If the number of interleaved code symbols is 15,360 and the data rate (or code rate) of sub-codes is given as 307.2kbps, the QCTC generator 103 generates
 20 the first sub-code having 21,504 symbols by taking the 15,360 interleaved code symbols and repeating part of the first half of the interleaved code symbols. If the data rate is 614.4kbps, the QCTC generator 103 generates the first sub-code by taking the first 10,752 code symbols from the first half of the interleaved code symbols. And if the data rate is 1228.8kbps or 2457.6kbps, the QCTC
 25 generator 103 generates the first sub-code by taking the first 5,376 code symbols from the interleaved code symbols.

To generate a QCTC (or sub-codes), the channel interleaver 102 should take particular characteristics because the five symbols X , Y_0 , Y_1 , Y_0' , and Y_1'
 30 are distributed through channel interleaving and the distributed code symbols are

not suitable for the input of the QCTC generator 103 and because it is not easy to generate sub-codes satisfying the characteristics of a QCTC with the mixed symbols of X , Y_0 , Y_1 , Y_0' , and Y_1' . In this context, the present invention provides a method of generating a QCTC in a predetermined way irrespective of
 5 the code rate of each sub-code.

FIG. 2 is a block diagram of the QCTC generating apparatus according to an embodiment of the present invention.

10 Referring to FIG. 2, an encoder 201 generates code symbols by encoding input information symbols (i.e. input encoder packet). The encoder 201 uses a mother code with $R=1/5$ or with any other code rate. A mother code is determined by the system used. A turbo code with $R=1/5$ is used herein as a mother code by way of example. Then, the encoder 201 generates information
 15 symbols X , first parity symbols Y_0 and Y_0' and second parity symbols Y_1 and Y_1' by encoding input information symbols. The first parity symbols Y_0 and Y_0' are output from a first constituent encoder and the second parity symbols Y_1 and Y_1' from a second constituent encoder. The first and second constituent encoders (not shown) are contained in encoder 201. The primary parity symbols
 20 Y_0 and Y_1 from the first and second constituent encoders have a higher transmission priority than the secondary parity symbols Y_0' and Y_1' .

A demultiplexer (DEMUX) 202 groups the code symbols received from the encoder 201 into information symbols X 203, parity symbols Y_0 213, parity
 25 symbols Y_1 223, parity symbols Y_0' 233, and parity symbols Y_1' 243 and outputs the five symbol groups to corresponding respective interleavers 204, 214, 224, 234 and 244.

Interleavers 204, 214, 224, 234 and 244 randomly permute the sequences
 30 of the input code symbols by interleaving. Various interleaving methods are

available as long as the following condition is satisfied.

(Condition) Interleaved code symbols are partially punctured in such a way that the puncturing pattern of code symbols before interleaving has a
5 uniform puncturing distance.

The reason for satisfying the above condition is that when code symbol groups X , Y_0 , Y_1 , Y_0' , and Y_1' are punctured in the same number of code symbol positions, the distance between punctured code symbol positions in the code
10 symbols before interleaving must be equal to achieve optimum turbo code performance. In other words, when puncturing is applied to turbo codes, uniformity is a significant factor that determines the performance of the turbo codes. In accordance with the present invention, sub-block interleaving applies independently to the code symbols X , Y_0 , Y_0' , Y_1 , and Y_1' . Uniform puncturing
15 in each interleaver output maintains an equal distance between punctured code symbols in encoder output. Therefore, it can be concluded that channel interleaving must be chosen so that puncturing in interleaved code symbols can maintain a uniform puncturing distribution in channel encoder output.

20 Such channel interleaving methods include bit reversal order (BRO) interleaving and partial bit reversal order (PBRO) interleaving. The BRO interleaving is practicable only if the number of input information symbols to an encoder and the number of each code symbol set X , Y_0 , Y_0' , Y_1 , and Y_1' are powers of 2, that is, 2^m wherein m is a parameter to make a block size of sub
25 block interleaver such as block size $N=2^m \cdot J$.

The PBRO interleaving was designed to satisfy the afore-stated condition even if the number of information symbols and the number of each encoder output symbol set X , Y_0 , Y_0' , Y_1 , and Y_1' are not powers of 2 in order to
30 overcome the limitation of the BRO interleaving. A detailed description of this

sub-block channel interleaving will be avoided here and it is to be noted that any channel interleaving method can be implemented in the present invention as long as it satisfies the above condition.

5

The interleaved code symbols X 206 (shown as a block for convenience) output from the first interleaver 204 are applied directly to the input of a symbol concatenator 207. The interleaved code symbols Y_0 and Y_1 from the second and third interleavers 214 and 224 are input to a first multiplexer (MUX) 205 and
10 the interleaved code symbols Y_0' and Y_1' from the fourth and fifth interleavers 234 and 244, to a second MUX 215. That is, the first MUX 205 receives the primary parity symbols and the second MUX 215 receives the secondary parity symbols.

15 The first MUX 205 multiplexes the interleaved parity symbols Y_0 and Y_1 216 and feeds the output to the symbol concatenator 207. The second MUX 215 multiplexes the interleaved parity symbols Y_0' and Y_1' 226 and feeds its output to the symbol concatenator 207. That is, the MUXes 205 and 215 multiplex the parity symbol sequences by priority level. With the aid of the
20 MUXes 205 and 215, the interleaver outputs are rearranged and then divided into three sub-groups, 206, 216 and 226.

The above-described process, which is essential to generation of QCTCs according to the present invention, will be described in more detail. As shown
25 in FIG. 2, information symbols X form an independent sub-group without passing through multiplexing after sub-block interleaving. Let the sub-block interleaved symbols be Sb_i_X , which can be expressed as

$$Sb_i_X(1), Sb_i_X(2), Sb_i_X(3), Sb_i_X(4) \dots$$

..... (1)

where $Sb_i_X(1)$ indicates the first code symbol output from the first interleaver 204. Sb_i_X is referred to as sequence A.

5

Then, the interleaved code symbols Y_0 and Y_1 output from the second and third interleavers 214 and 224 are grouped into one sub-group. If the code symbols Y_0 are $Sb_i_Y_0$, $Sb_i_Y_0$ can be expressed as

10 $Sb_i_Y_0(1), Sb_i_Y_0(2), Sb_i_Y_0(3), Sb_i_Y_0(4) \dots$
..... (2)

where $Sb_i_Y_0(1)$ indicates the first code symbol output from the second interleaver 214. If the code symbols Y_1 are $Sb_i_Y_1$, $Sb_i_Y_1$ can be expressed as

15 $Sb_i_Y_1(1), Sb_i_Y_1(2), Sb_i_Y_1(3), Sb_i_Y_1(4) \dots$
..... (3)

where $Sb_i_Y_1(1)$ and $Sb_i_Y_1(2)$ indicate the first and second code symbols respectively, output from the third interleaver 224. After multiplexing the code symbols Y_0 and Y_1 ,

20 $Sb_i_Y_0(1), Sb_i_Y_1(1), Sb_i_Y_0(2), Sb_i_Y_1(2), Sb_i_Y_0(3), Sb_i_Y_1(3) \dots$
..... (4)

These multiplexed symbols are referred to as sequence B.

25 The reason for multiplexing the interleaved code symbols $Sb_i_Y_0$ and $Sb_i_Y_1$ is that when M successive symbols are punctured in the sequence B irrespective of the first half or second half of the sequence B, the number of punctured symbols in $Sb_i_Y_0$ is equal to that of punctured symbols in $Sb_i_Y_1$ only if M is an even number. If M is an odd number, the difference between the

numbers of punctured symbols in $Sb_i_Y_0$ and in $Sb_i_Y_1$ is only 1. The multiplexing always satisfies the QCTC characteristic that the number of punctured parity symbols Y_0 is equal to that of punctured parity symbols Y_1 .

5

In the same manner, the interleaved code symbols Y_0' and Y_1' output from the fourth and fifth interleavers 234 and 244 are grouped into one sub-group. If the code symbols Y_0' and Y_1' are $Sb_i_Y_0'$ and $Sb_i_Y_1'$, respectively, $Sb_i_Y_0'$ and $Sb_i_Y_1'$ can be expressed as

10

$$Sb_i_Y_0'(1), Sb_i_Y_0'(2), Sb_i_Y_0'(3), Sb_i_Y_0'(4) \dots \dots \dots (5)$$

and

15

$$Sb_i_Y_1'(1), Sb_i_Y_1'(2), Sb_i_Y_1'(3), Sb_i_Y_1'(4) \dots \dots \dots (6)$$

Then, the output of the second MUX 215 is

20

$$Sb_i_Y_0'(1), Sb_i_Y_1'(1), Sb_i_Y_0'(2), Sb_i_Y_1'(2), Sb_i_Y_0'(3), Sb_i_Y_1'(3) \dots \dots \dots (7)$$

These multiplexed symbols are referred to as sequence C.

The reason for multiplexing the interleaved code symbols $Sb_i_Y_0'$ and $Sb_i_Y_1'$ is that when M successive symbols are punctured in the sequence C
25 irrespective of the first half or second half of the sequence C, the number of punctured symbols in $Sb_i_Y_0'$ is equal to that of punctured symbols in $Sb_i_Y_1'$ only if M is an even number. If M is an odd number, the difference between the numbers of punctured symbols in $Sb_i_Y_0'$ and in $Sb_i_Y_1'$ is only 1. The multiplexing always satisfies the QCTC characteristic that the number of

punctured parity symbols Y_0' is equal to that of punctured parity symbols Y_1' .

The symbol concatenator 207 sequentially concatenates the sequences A, B and C of the first, second, and third sub-groups and generates a symbol
5 sequence [A:B:C].

$$[A:B:C] = [Sb_i_X(1), Sb_i_X(2), Sb_i_X(3), \dots] [Sb_i_Y_0(1), Sb_i_Y_1(1), Sb_i_Y_0(2), Sb_i_Y_1(2), \dots] [Sb_i_Y_0'(1), Sb_i_Y_1'(1), Sb_i_Y_0'(2), Sb_i_Y_1'(2), \dots] \dots \dots (8)$$

10

As seen from the above formula, information symbols are placed first, followed by alternating parity symbols Y_0 and Y_1 and then by alternating parity symbols Y_0' and Y_1' in the sequence [A:B:C]. This symbol arrangement assumes a very significant meaning in QCTC generation, which will be described
15 below.

Puncturing should be carried out to generate a sub-code with a code rate from the turbo code of (8). The puncturing is defined by a "QCTC". The QCTC should have the following characteristics.

20

(1) Information symbols precede all other code symbols in transmission. Especially, as the code rate of sub-codes is close to 1, this characteristic becomes more important.

25

(2) A puncturing pattern is formed so that the number of parity symbols output from each constituent encoder (a first constituent encoder and a second constituent encoder) is equal or their difference in number is minimum.

(3) The number of punctured symbols in the parity symbols Y_0 and Y_0' is

determined such that the code rate of the first constituent encoder is always less than 1. That is, the performance of turbo codes is ensured when at least one parity symbol Y_0 or Y_0' exists.

5

(4) The distance between punctured symbols in a QCTC resulting from puncturing is equal.

(5) A turbo code produced by combining sub-codes of QCTCs assumes
10 the characteristics of a quasi-complementary code.

A QCTC with a sub-code code rate, which is generated by puncturing or pruning as many symbols as necessary from the end of the symbol sequence [A:B:C], satisfies the above five characteristics. In other words, an intended
15 sub-code of a QCTC is generated by repeating and puncturing as many symbols as needed in the symbol sequence [A:B:C] in a symbol sequence repeater 208 and a symbol puncturer 209. The symbol sequence repeater 208 repeats the symbol sequence received from the symbol concatenator in a predetermined way. The repetition method is determined according to the code rate of the sub-code.
20 The symbol puncturer 209 punctures or prunes as many symbols as a predetermined number, starting with the last symbol in the symbol sequence received from the symbol sequence repeater 208, to thereby create the sub-code of the QCTC. The number of punctured symbols depends on the code rate of the sub-code. Therefore, the code rate of the sub-code should be provided to
25 the symbol sequence repeater 208 and the symbol puncturer 209 in order to perform sequence repetition and symbol puncturing. Alternatively, a higher layer controller (not shown) can calculate the number of repeated symbols and the number of punctured symbols according to a mother code rate and a sub-code rate and feed the information to the symbol sequence repeater 208 and the
30 symbol puncturer 209.

In other words, the symbol puncturer 209 selects a predetermined number of symbols counted from a given symbol position in the symbol sequence received from the symbol sequence repeater 208, thereby generating the sub-code of the QCTC. The given symbol position refers to the symbol next to the last symbol selected for the previous transmission. Therefore, the symbol puncturer 209 can be called a “symbol selector”.

The interleavers 203, 213, 223, 233 and 243, the MUXes 205 and 215, and the symbol concatenator 207 in FIG. 2 correspond to the channel interleaver 102 in FIG. 1, and the symbol sequence repeater 208 and the symbol puncturer 209 both correspond to the QCTC generator 103.

Returning to FIG. 1, assuming a mother code rate $R=1/5$ and 3,072 input information bits, the channel encoder 101 outputs 15,360 code symbols. Herein below, there will be a description of generating QCTCs with different code rates (or data rates), for example, a first QCTC C_{0j} at 307.2kbps, a second QCTC C_{1j} at 614.4kbps, and a third QCTC C_{3j} at 1288.8kbps, from the code symbols.

As described before, the 15,360 code symbols are classified into five sub-groups, interleaved, and then rearranged as the symbol sequence of Eq. (8). Then, the 15,360 code symbols are subject to repetition according to a predetermined rule and puncturing (or pruning) according to a predetermined sub-code code rate. Thus, an intended sub-code is generated.

25

For a data rate of 307.2kbps, if the sub-codes of the first QCTC C_{0j} are 21,504 bits in length, the first sub-code C_{00} is generated by selecting the first 21,504 symbols from the interleaved and repeated symbol sequence. The second sub-code C_{01} is generated by selecting 21,504 symbols starting with the symbol following the first sub-code C_{00} from the repeated symbol sequence.

30

The third sub-code C_{02} is generated by selecting the following 21,504 symbols.

Similarly, for a data rate of 614.4kbps, if the sub-codes of the second QCTC C_{1j} are 10,752 bits in length, the first sub-code C_{10} is generated by selecting the first 10,752 symbols from the repeated symbol sequence. In other words, the first sub-code C_{10} is generated by pruning all subsequent symbols following the first 10,752 symbols in the repeated symbol sequence. The pruning is performed in the symbol puncturer 209 as stated before. The second sub-code C_{11} is generated by selecting 10,752 symbols starting with the symbol following the first sub-code C_{10} from the repeated symbol sequence. The third sub-code C_{12} is generated by selecting the 10,752 symbols following the second sub-code C_{11} .

Similarly, for a data rate of 1228.8kbps, if the sub-codes of the third QCTC C_{2j} are 5,376 bits in length, the first sub-code C_{20} is generated by selecting the first 5,376 symbols from the repeated symbol sequence. The second sub-code C_{21} is generated by selecting 5,376 symbols starting with the symbol following the first sub-code C_{20} from the repeated symbol sequence. The third sub-code C_{22} is generated by selecting the following 5,376 symbols. In this manner, the sub-codes of the QCTC at 1228.8kbps are generated.

The system stores information about the position of the last symbol in the previous transmitted sub-code for each QCTC. When a data rate (or code rate) for retransmission is determined, the system selects a QCTC corresponding to the data rate and generates a sub-code by selecting a predetermined number of symbols following the stored last symbol for the selected QCTC according to the data rate. If the selected symbols exceed one interleaved symbol block, the remaining symbols are selected from the following block. In this case, sub-codes are generated by repeating a block of interleaved symbols. To do so, a storing area is needed to store the repeated blocks.

Alternatively, the interleaved symbols can be stored in a circular buffer memory and a sub-code is generated by selecting symbols recursively. That is, if interleaved symbols are all selected, a predetermined number of symbols are
 5 selected from the interleaved symbols starting with the first symbol. Then, the symbol sequence repeater 208 can be omitted since the circular buffer memory functions as the symbol sequence repeater 208.

The above embodiment of the present invention describes two-
 10 dimensional QCTCs. In the two-dimensional QCTC scheme, a QCTC corresponding to each code rate is generated independently and the sub-codes of the QCTC are sequentially transmitted. However, the two-dimensional QCTCs are not optimum for the reasons described below.

As shown in FIG. 2, it is assumed that the first sub-code C_{00} of the first QCTC C_{0j} is used for initial transmission, the first sub-code C_{10} of the second QCTC C_{1j} is used for the next transmission, and the first sub-code C_{20} of the third QCTC C_{2j} is used for the third transmission. Then, a receiver decodes data by combining the three sub-codes (C_{00} , C_{10} , C_{20}). In this case, however, the code
 20 combining does not recover an original code with a code rate of $1/5$, only to increase the symbol energy of information symbols and thus not to optimize decoding performance. This implies that there is a problem with the transmission order of the sub-codes, that is, selection of the sub-codes. To overcome the problem, adaptive QCTCs are proposed. In the adaptive QCTC
 25 scheme, the number of code symbols to be selected is determined according to the code rate of a sub-code, and the sub-code is generated by selecting the determined number of symbols starting with the symbol following the last symbol used for the previous transmission.

FIG. 3 is a block diagram of another embodiment of the QCTC

generating apparatus. The structure shown in FIG. 3 is the same as that shown in FIG. 2 except that the symbol sequence repeater and the symbol puncturer operate in different manners. Therefore, the following description is made mainly of the symbol sequence repeater 308 and the symbol puncturer 309.

5

The symbol sequence repeater 308 repeats a symbol sequence received from a symbol concatenator 307 in a predetermined way. The repetition may be carried out according to a given parameter in the symbol sequence repeater 308, or under the control of a higher layer controller (not shown), or upon request of
10 the symbol concatenator 307. The above process is implemented in the same manner as described referring to FIG. 2. Then, the symbol puncturer 309 punctures symbols received from the symbol sequence repeater 308 according to a different rule from the rule applied in FIG. 2 to generate a sub-code. The puncturing rule is as follows.

15

It is assumed that transmission starts at time k , a sub-code transmitted at time $(k+h)$ is expressed as $C_{ij}(k+h)$, and the code symbols of a mother code with $R=1/5$ are $C_m(0), C_m(1), \dots, C_m(N-1)$. The number of the code symbols, N , is defined as $L_INF \times 5$ since the mother code rate is $1/5$. Here, L_INF denotes the
20 size of a sub-block interleaver, or the number of information symbols.

Step 1: the length of an initial sub-code is determined.

For an initial transmission, one C_{i0} of the first sub-codes C_{00}, C_{10}, C_{20} of available QCTCs is selected according to a given code rate and the length of the
25 selected sub-code C_{i0} is stored as a variable L_SC . The code rate or length L_SC of the sub-code is predetermined in the system according to channel environment including transmission channel condition and input data rate. The description is made in the context of three QCTCs shown in FIG. 3 for better understanding of the present invention, but the number of sub-codes is not

limited.

Step 2: a sub-code for initial transmission is selected and transmitted.

After the length of a sub-code to be transmitted is determined, $C_m(0)$,
 5 $C_m(1), \dots, C_m(L_SC-1)$ are selected among the code symbols of the mother code.
 If L_SC exceeds N , $C_m(0), C_m(1), \dots, C_m(N-1)$ are transmitted P times and then
 $C_m(0), C_m(1), \dots, C_m(q-1)$ are transmitted. Here, P and q are the quotient and
 remainder of L_SC/N , respectively and P and q are calculated by $L_SC \bmod N$.
 Then, the variable q is stored for the next transmission for use in detecting the
 10 position of the last symbol of the previous transmitted sub-code with respect to
 the block of interleaved symbols.

Step 3: the starting position of a sub-code for the next transmission and
 the length of the sub-code are determined.

15 For the next transmission, the code rate R_SC of a new sub-code to be
 transmitted is determined according to channel environment and the length L_SC
 of the sub-code is determined according to the determined code rate. The
 length L_SC and the code rate R_SC is in the relation of

$$20 \quad L_SC = L_INF \times (1/R_SC) \dots \dots \dots (9)$$

A higher layer system transmits the sub-code length L_SC and the sub-code code
 rate R_SC to the symbol puncturer 309 for each transmission.

25 Step 4: a sub-code for the next transmission is selected and transmitted.

After the length L_SC of the sub-code to be transmitted is determined,
 $C_m(q), C_m(q+1), \dots, C_m(q+L_SC-1)$ are selected among the code symbols of the
 mother code. In other words, as many symbols as the sub-code length are
 selected from the mother code symbols starting with the symbol following the

last symbol selected for the previous transmission. If $q+L_SC$ exceeds N , a row comprised of N code symbols starting with $C_m(q)$ are selected recursively and transmitted P times and then the remaining q' code symbols are sequentially transmitted. Here, P and q' are the quotient and remainder of $(L_SC)/N$,
 5 respectively and the q' is calculated by $(q+L_SC) \bmod N$. Then, the next symbol position value of the position of the last selected symbol for the next transmission is stored to the q . The variable q is the next symbol position of the last symbol position among symbols comprised of the last transmitted sub-code. After the generated sub-code is transmitted, the procedure returns to step 3.

10

The transmission of adaptive QCTCs will be made clear with cases shown in FIG. 3. Referring to FIG. 3, a low rate sub-code with a code rate of $1/7$ is initially transmitted in Case 1, and a high rate sub-code with a code rate of $4/7$ is initially transmitted in Case 2. As seen from the cases, $N (=15,360)$
 15 successive mother code symbols are repeated and as many code symbols as a size corresponding to the length of a sub-code to be transmitted (or the code rate of the sub-code) are selected sequentially from the repeated mother code symbols, at each transmission.

20 In real implementation, a buffer is not used to store $(P-1)$ times repeated-mother codes, but a single circular buffer is employed to store N code symbols and recursively select code symbols to thereby generate a sub-code of an intended length. That is, use of the circular buffer memory obviates the need of sequence repetition. Any reception buffer is available to a receiver as long as it
 25 can store N soft metrics for code combining.

While the invention has been shown and described with reference to certain preferred embodiments thereof, it will be understood by those skilled in the art that various changes in form and details may be made therein without
 30 departing from the spirit and scope of the invention as defined by the appended

claims.
